# Compsopogon coeruleus, a red alga newly reported for freshwater aquaria in Prague

Compsopogon coeruleus, sladkovodní ruducha žijící v pražských akváriích

Jacques S. Zaneveld, Bohuslav Fott and Marcela Nováková

Zaneveld J. S.<sup>1</sup>), B. Fott<sup>2</sup>) et M. Nονάκονά<sup>2</sup>) (1976): Compsopogon coeruleus, a red alga newly reported for freshwater aquaria in Prague. — Preslia, Praha, 48:17—20.

Examination of a dense growth of erect, bluish green filaments in some freshwater aquaria in Prague, Czechoslovakia, revealed that these thalli were a red algal species, Compsopogon coeruleus (Balbis) Montagne. Since this species is essentially tropical and subtropical and it has been rarely reported from Europe, the new locality constitutes an interesting extension of its known distribution. A diagnosis of this species as well as some details about its morphology and geographical distribution are given.

#### INTRODUCTION

A dense growth of blue to blue green colored algal filaments growing on stones, waterplants, and the bottom of some aquaria in Prague turned out to be a red algal species of the genus Compsopogon. This is an essentially world wide distributed mainly tropical and subtropical fresh and brackish water genus. According to the monograph of the genus by Krishnamurthy (1962) and some additional papers the genus is represented in India (Krish-NAMURTHY 1957, Das 1964), the Malayan Archipelago (Weber-Van Bosse 1921-1928), the Antilles (Taylor 1960), Italy (Meneghini 1840), Algeria (Montagne 1846), France (Boillot 1958), and the southern U.S.A. (Smith 1950). However, some Compsopogon species have also been reported from localities with a temperate climate, i.e. China (Jao 1941), Japan (Okamura 1915), the Northern U.S.A. (Collins 1916, Smith 1950), Great Britain (Weiss et Murray 1909), Germany (Friedrich 1966), and New Zealand (Chapman et Cameron 1967). The occurrence of the species in these localities which is thought to be due to transport by shipping, is often characterized by an influx of warm waste water.

First in 1961 by MÜLLER, and again in 1971 by HEYNIG a Compsopogon species was reported from Germany inhabiting warmwater aquaria. From their original habitats these species may have been introduced into Central Europe by the transfer of aquarium plants. Such a transfer of tropical plants is also held responsible for the invasion of the tropical green alga, Pithophora into Czech aquaria (Šula 1930, Fott 1971).

The dimensions of the aquarium of Dr. Pecina in Prague were  $70 \times 34 \times 32$  cm. The alga was growing here before 1971. After that year the species disappeared suddenly for two years but has developed recently (in 1975) again. The bottom of the aquarium is partly covered by gravel which has not changed over the last five years and partly of isolated pieces of limestone which are deposited in the background of the aquarium. Here, some submerged plants belonging to the genus Cryptocoryne are growing on which the spores of Compsopogon germinate and develop as

germlings. The adult algae are usually up to 10 cm long and are not damaged by herbivorous fish, as long as the algae are alive and growing. Their habit is well adapted to the plantation of *Cryptocoryne* or other water plants. The alkalinity of the aquarium water measures 1.76 meq/l and the pH of the sample equilibrated with air was 7.9. The temperature of the water in summer is from 24 to 25° C, in winter it is not below 20° C. The aquarium was inhabited by a rather great amount of fish. Out of about 60 specimens of fish one third were adults belonging to the species *Poecilia melanogaster*, *Xiphophorus maculatus*, and *Girardinus metallicus*. The aquarium was not aerated.

### MORPHOLOGY, REPRODUCTION, AND TAXONOMIC POSITION

The Compsopogonaceae occupy an unique position among the primitive red algae in that the erect axis consists of large colorless, axial cells surrounded by 2—4 layers of small, densely pigmented cortical cells (Pl. I:2). With the exception of the Compsopogonaceae all other Bangiophycidae lack a cortical envelope.

Contrary to the observations by Fan (1960) studies with the electron microscope have shown that the cell walls of *Compsopogon* are without pit connections (Nichols, Ridgway et Bold 1966). The openings seen in incompletely deposited cell walls are not similar to the pit connections in the *Florideophycidae*. However, in such cases cytoplasmatic connections between adjacent cells occur and typical cell organelles, including chloroplasts, are

contained within the cytoplasm.

The blue green chloroplasts are parietal and so closely associated as to form irregularly winded, lobed, rosary shaped structures (Pl. I:4). In older cells the chloroplasts are separated and no longer ensheathed by cytoplasmatic strands. In mature cells there is a great number of vacuoles but in young cells there is just a single large one. The nucleus is rather conspicuous and located on one side of the cell (Pl. I:4). In older cells a dense accumulation of floridean starch grains fills the cells.

Normally, reproduction is by means of monospores (= macroaplanospores). Any cortical cell of an old filament may become a monosporangium. Upon germination the monospores develop a prostrate system of branching filaments from which the erect, corticated filaments may arise. In some cases

microaplanospores may be formed (Thaxter 1900).

The Rhodophyta form an ancient group of algae. Fossil records of possible red algae are known from the Paleozoic era which started about 600 million years ago. The division contains only one class, the Rhodophyceae which is subdivided into two subclasses, i.e. the more primitive Bangiophycidae and the higher developed Florideophycidae. According to Skuja (1939) there are 7 families in the Bangiophycidae, one of which is the family Compsopogonaceae. In his monograph, Krishnamurthy recognized two genera, Compsopogon and Compsopogonopsis. The former includes all algae with coarse axes exceeding 250 µm in diameter and with rhizoidal outgrowths confined to the basal part of the thallus only.

#### DIAGNOSIS OF THE CZECH AQUARIUM SPECIMENS

Thallus bushy, soft but not gelatinous, sessile or free floating, green to bluish-violet green; sessile plants with small basal attachment cells from which uniseriate,  $4-6~\mu m$  wide rhizoids project into the substrate and from which usually one but sometimes 2-4 erect, well branched filaments arise; branches making a wide angle (usually over  $70^\circ$ ) with the main axis; erect filaments variable in length but normally less than 10 cm long and up to 0.5 mm wide; older parts cylindrical but tapering to uniseriate branches with blunt tips; older parts 0.4–1 mm in diameter; uniseriate branches consisting of discoid cells which measure at the base 17–26  $\mu m$  wide  $\times$  10

to 18  $\mu m$  high and at the apices 4—7  $\mu m$  wide  $\times$  3—6  $\mu m$  high; older filaments and branches corticated; cortex usually forming more than one layer; cortical cells triangular to polygonal, outer cells 18—34  $\mu m$  wide and 12—21  $\mu m$  high; axial cells 126—175  $\mu m$  wide and 42  $\mu m$  high; monosporangia 21—25  $\mu m$  in diameter; monospores (only macro-aplanospores were seen) average 17  $\mu m$  in diameter.

### DISCUSSION

The measurements given in the diagnosis indicate that the Czech aquarium specimens have to be referred to Compsopogon coeruleus (Balbis) Montagne. The thallus is relatively short (shorter than in wild live specimens) and the erect axes are up to only 0.5 mm wide. Under the microscope, most impressive are the outstanding branches making an angle with the main axis of close to 90°. The dimensions of the cells of the uniseriate branches, of the cortical cells, and of the monosporangia agree with those of C. coeruleus. However, it is certainly true that the differences between C. coeruleus and C. hookeri Montagne are relatively slight (Chapman et Cameron 1967). The other closely related species, C. aeruginosus (J. Agardh) Kützing has smaller monospores being  $9-13~\mu m$  in diameter and the axes bear short spinous branches. Both characteristics are absent in our specimens.

C. coeruleus is the most widespread species of the genus. It has been recorded from all continents and from localities other than the tropics and subtropics. The species occurs in both fresh and brackish water, from sea level to 1200 meters above sea level. It has become a nuisance in some irrigation works (SMITH 1950). It is unlikely that this could happen in Czechoslovakia since the period of cold weather is too long for this alga to make survival possible. Because of the low winter temperatures it is also unlikely that the alga will become a permanent member of the Czech algal flora. In aquaria, Compsopogon if present in reasonable quantities, is certainly useful while releasing oxygen by photosynthesis.

C. coeruleus is the type species of the genus. The species was first described by Montagne (1846) from a specimen collected in Algeria. Another specimen, mounted on the same herbarium sheet, is a specimen from the herbarium of Balbis and was collected in Puerto Rico. The former specimen is designated as the type, the second as co-type. The type specimen is present in the Muséum National d'Histoire Naturelle, Paris.

#### ACKNOWLEDGEMENT

Our thanks are due to Dr. P. Pecina (Prague) who observed an unknown alga growing in his own aquarium and gave us live material for study. One of us (J.S.Z) would like to thank the Czechoslovak Academy of Sciences and the Head of the Department of Botany of Caroline University, both at Prague, for their hospitality and aid during his stay in Czechoslovakia as an exchange scientist with the U.S. Academy of Sciences, Washington, D. C.

#### SOUHRN

Compsopogon Montagne 1846 je rod sladkovodních ruduch, obsahující 6 druhů (Krishnamurthy 1962), které jsou kosmopolitně rozšířeny v teplých vodách trópů a subtrópů. Jeden druh, řazený původně do rodu Lemanea, je znám i z jižní Evropy z okolí města Pisy v Itálii. Nejrozšířenější druh Compsopogon coeruleus (Balbis) Montagne se počíná v posledních 20 letech šířit i do chladnějších částí Evropy. První nález byl v umělém toku Reddish Canal u města Manchester v Anglii. Kanál se vyznačuje zvýšenou teplotou vody po celý rok a byla v něm již dříve objevena jiná tropická sladkovodní zelená řasa Pithophora. Další nálezy ruduchy jsou z teplých odpadních vod v NSR (Friedrich 1966) a z akvárií v NDR (Heynig 1971). V Praze ji ve svém akváriu poprvé nalezl dr. P. Pecina v r. 1971 a dal nám materiál k prostudování. Vedle rodu Pithophora, která ve sterilním stavu se sotva dá rozlišit od r. Cladophora, je to druhý obyvatel tropických vod zdomácnělý v našich akváriích. V mládí má Compsopogon podobu krátkých, jednořadých vláken modrozelené, našedlé barvy, rostoucích na akvarijních rostlinách. Později vyroste keříčkovitě větvená stélka, několik centimetrů velká (v přírodě až 20 cm, v našich akváriích asi 9 cm), která se může oddělit od podkladu a volně vzplývat ve vodě. Na průřezu stélkou vidíme sloupec vel-

kých osních buněk, obklopený parenchymatickou korou drobných buněk. Plastidy v buňkách obsahující asimilační pigmenty nejsou červené, jak bychom u ruduchy očekávali, nýbrž šedomodré. Modrý fykocyanin převládá nad malým množstvím červeného fykocrythrinu. Na rozdíl od ostatních řas, znečišťujících stěny a rostliny akvarií, dá se *Compsopogon* snadno odstranit a v přiměřeném množství zásobuje akvarijní vodu vydatně kyslíkem. Rozmnožuje se tvorbou nepohlavních spor, tzv. monospor. Potvrdili jsme elektronoptická pozorování (Nichols et al. 1966), že zrněčka škrobu jako u všech ruduch se tvoří v cytoplasmě a hromadí se zvláště kolem elipsoidního jádra, které se následkem toho podobá pyrenoidu (Pl. I: 4).
